### Abstract

This research focused on optimizing the removal process of the harmful element lead (Pb) in various stages of copper production (flash smelting, copper converting, and thermal refining). The present study used a factorial design of experiments to investigate the effects of various parameters, including reheating and the use of various slag-forming agents, including CaO, MgO, SiO<sub>2</sub>, Na<sub>2</sub>CO<sub>3</sub>, and Na<sub>2</sub>SO<sub>4</sub>, on the removal rate of this harmful element. Initially, thermodynamic calculations showed that increasing the temperature does not significantly accelerate Pb removal, and the use of slag-forming agents for this purpose is essential. In the flash furnace, the results showed that adding Na<sub>2</sub>SO<sub>4</sub> has the greatest effect on reducing the amount of Pb in the matte, followed by MgO. Microstructural studies of blister copper and converter furnace slag indicated that although a portion of Pb can be removed through the slag, the remaining amounts of this element in blister copper are still significant. Therefore, relying on reheating or slag-forming agents alone is not sufficient at this stage. In the matte blowing stage, the presence of slag-forming agents SiO<sub>2</sub> and Na<sub>2</sub>SO<sub>4</sub> helped reduce Pb by forming stable compounds in the slag, and therefore, the use of this combination was introduced as an effective method for separating Pb due to the creation of favorable chemical reactions and the formation of sodium Pb silicate. In the anode furnace, SiO<sub>2</sub> had the greatest effect on Pb removal, and the simultaneous presence of CaO-MgO-Na<sub>2</sub>CO<sub>3</sub> and MgO-Na<sub>2</sub>SO<sub>4</sub>-SiO<sub>2</sub> also produced very good results. Experimental studies and statistical analyses showed that the anode furnace is the best stage for removing the element Pb before electrolytic refining due to the process conditions. The optimal levels of slag-forming agents were also determined in this stage. The results showed that in the presence of slag-forming agents CaO-MgO-Na<sub>2</sub>CO<sub>3</sub> and MgO-Na<sub>2</sub>SO<sub>4</sub>-SiO<sub>2</sub>, very good results in terms of lead reduction (more than 79%) were achieved. Overall, this research provided valuable information on how to remove the element Pb from copper in various stages of production and can be used to optimize copper production processes and improve the quality of the final product.

## 1. INTRODUCTION

The passivation of the copper anode during the electrorefining process is a widespread challenge in this stage [1–4]. This phenomenon

depends on several physical and chemical factors, including the nature of the anode slime, the chemical composition of the anode and electrolyte solution, the applied electric current density, the electrolyte temperature, and the

chemical composition of the non-conductive layers formed on the anode surface [4–7]. Reducing the applied electric current density, and consequently reducing the production of pure copper, increasing power consumption, and reducing cathode quality due to increased floating slime are among the consequences of copper anode passivation [7,8]. To prevent such problems, it is necessary to prevent the formation of anode slime or to remove impurities that cause these slimes [9].

Commercial copper anodes typically contain significant amounts of certain impurities, particularly arsenic, bismuth, antimony, nickel, iron, Pb, selenium, tellurium, sulfur, as well as precious metals such as gold and silver [10,11]. Although the overall concentration of these impurities within the anode may be less than one weight percent, even these small amounts of certain impurities can significantly affect the anode behavior and the copper electrorefining process [12]. Arsenic, antimony, and bismuth, along with oxygen, are impurities that play a significant role in anode passivation and anode slime formation [8,11,13,14]. On the other hand, Pb is one of the elements that is abundantly found in copper sulfide ores and does not have a significant effect on the electrical or thermal conductivity of copper and its alloys. However, the presence of Pb in copper increases the volume of anode slime during the electrorefining process [15], and for this reason, many studies have been conducted to remove Pb during the copper smelting process [16–19].

The injection of clean concentrate into converters is also commonly used to improve efficiency and as a suitable solution for removing more impurities. This method is only valid if a clean concentrate (free of trace amounts of lead, bismuth, arsenic, and antimony) can be injected into the system, and faces serious limitations [20]. In the meantime, the use of slag-forming agents has also been accepted as a main solution. For example, Heo et al. [21] investigated the distribution coefficient of Pb between slag and molten copper at a temperature of 1473 K. They found that by increasing the  $Al_2O_3$  content in the slag, the activity of FeO decreases, and this leads to better dissolution of Pb in the slag [34]. In another study, the effect of the weight percentage of copper in the matte on the distribution coefficient of impurities between slag and matte was investigated. The results of this study also showed that with increasing copper content in the matte, the distribution coefficient between slag and matte for copper, zinc, and lead increases [22].

Despite the research carried out to remove the element Pb, it should be noted that a small amount of Pb still remains in the copper anode, which can cause problems in the electrolytic refining stage. One of the possible solutions to minimize the harmful effects of this harmful element is to remove it during the smelting and production of copper anodes and prevent it from entering the copper electrorefining process. Therefore, this research attempts to investigate the optimal conditions for removing the element Pb during the various stages of thermal refining of copper by performing a factorial design of experiments. For this purpose, the effect of the presence of various slag-forming agents such as CaO, MgO,  $SiO_2$ ,  $Na_2CO_3$ , and  $Na_2SO_4$  on the removal rate of this harmful element was investigated.

## 2. MATERIALS AND METHODS

### 2.1. Sampling

Sampling of concentrate, flash furnace dust, matte, and slag from the furnace was performed at 5-hour intervals. Concentrate destined for the smelting unit of the Sarcheshmeh Copper Complex is fed into concentrate storage tanks by a conveyor belt, which also controls the rate of transfer to the cooler and then to the flash furnace burner. It should be noted that sampling of the concentrate entering the flash furnace is only feasible from the belt feeding the aforementioned tanks. Additionally, concentrate entering the storage tanks enters the flash furnace approximately three hours later. As soon as the concentrate enters the flash furnace, dust from the concentrate becomes part of the melting boilers; however, the formation of matte and slag requires at least one hour. Consequently, sampling of concentrate, flash dust, matte, and slag exiting the flash furnace was performed according to Table 1 at 5-hour intervals.

**Table 1. Name, code, and sampling time of the concentrate entering the flash furnace, boiler dust, and outlet matte**

| No. | Sample name                    | Sample code | Sampling time (h)  |
|-----|--------------------------------|-------------|--------------------|
| 1   | Concentrate entering the flash | C0          | Time origin (zero) |

From the four stages described above, a total of 21 samples were prepared and subjected to compositional analysis to examine the changes and distribution of impurity elements at each stage. To capture a reliable range of variations, multiple samples were considered. Using the data from this study, a mass-balance calculation was performed to determine the contributions of impurity elements in the dust and in the exhaust gas from the smelting plant (acid plant feed gas). Sampling was conducted separately for the converter and the anode in accordance with Table 2.

| Optimal slag-forming agent 1 | 20% less than stoichiometry | stoichiometry | 20% more than stoichiometry |
| Optimal slag-forming agent2  | 20% less than stoichiometry | stoichiometry | 20% more than stoichiometry |

Tables 5 to 7 present the parameters and their levels for the first-stage (screening) experimental

## 2.2. Experimental Design (DOE)

The effect of adding alloying elements on the solubility of impurity elements in the matte exiting the flash furnace was studied through remelting (Just Heat) and slag-making experiments by incorporating the relevant chemical compositions into the slag.

To study the effect of adding different compounds to the slag-forming agent, the slag-making process was conducted with the melt held stationary in the furnace at a temperature of 1250 °C. In addition, the effect of increasing the melt temperature to 1300 °C was also investigated. It should be noted that, in all cases, the impurity-element removal experiment was repeated only once in the Just Heat mode, while in other modes (adding slag-forming materials), the experiments were repeated twice. The slag-forming agents selected in this study were CaO, Na<sub>2</sub>CO<sub>3</sub>, SiO<sub>2</sub>, Na<sub>2</sub>SO<sub>4</sub>, and MgO.

In DOE, slag-forming additives were treated as the factors, and the percentage of impurity elements as the response. Given the large number of potential slag-forming agents, the initial stage employed screening to optimize the chosen slag-forming agent and to examine the levels of their variation. This was conducted at two levels: presence or absence of the slag-forming agent (Table 3).

**Table 3. Parameters and levels selected in the first stage of experimental design (screening)**

| Factors                         | Levels |        | Amount of compound at second level (high level) |
|---------------------------------|--------|--------|---|
|                                 | First  | Second |   |
| CaO                             | 0      | 1      | 0.12  |
| Na <sub>2</sub> CO <sub>3</sub> | 0      | 1      | 0.24  |
| SiO <sub>2</sub>                | 0      | 1      | 0.0059  |
| Na <sub>2</sub> SO <sub>4</sub> | 0      | 1      | 0.33  |
| MgO                             | 0      | 1      | 0.088   |

Following the screening, to identify the optimal slag-forming agent, the second stage employed a full factorial design at three levels (Table 4).

design for the matte, white metal, and anodic copper samples, respectively.

**Table 5. Partial factorial experiment design for Matte samples (screening)**

| Run     | Factor 1 | Factor 2 | Factor3                            | Factor4                            | Factor 5            |

### 2.3. Chemical-Composition Analysis Of Impurities

The weight percentages of impurity elements were measured by inductively coupled plasma (ICP) analysis. The instrument used was a Varian 715-ES ICP, capable of detecting elements at sub-ppm levels.

## 3. RESULTS AND DISCUSSION

### 3.1. Flash-Furnace

Table 8 shows the chemical composition of feed concentrate in the Sarcheshmeh copper complex. As seen, the amount of Pb in the concentrate is 0.09 wt.%. Also, the amount and distribution of Pb in the matte production stage in the flash furnace, as well as the chemical composition of dust, matte, and flash furnace slag, are presented in Table 9. The results show that 59% of the input Pb is accumulated in the exhaust gas, 32% is retained in the matte, and 9% is found in the slag. Additionally, the cooling of the furnace exhaust gas in the heat-recovery boilers causes the majority of lead exiting the furnace to settle in the dust phase.

**Table 9. Circulation of impurity elements in the flash furnace of Sarcheshmeh Copper Complex (wt.%)**

| Element | In matte | In slag | In exhaust gas |                       |
|---------|----------|---------|----------------|-----------------------|
|         |          |         | In gas phase   | In solid phase (dust) |
| Pb      | 32       | 9       | 21             | 38                    |

Table 10 shows the results of experiments on the effect of adding various compounds to molten and matte copper slag. As presented,  $\text{Na}_2\text{SO}_4$  has the strongest effect. Following  $\text{Na}_2\text{SO}_4$ ,  $\text{MgO}$  also produced a substantial reduction in Pb content in the matte exiting the flash furnace, decreasing it from 2094 ppm to 1830 ppm. Other added slag-forming compounds also contributed to reducing the lead content to a lesser extent.

**Table 10. Changes in the concentration of impurity elements in flash-furnace matte and slag due to the addition of slag-forming compounds**

| Additive to slag         | Melt  | Pb (ppm) |
|--------------------------|-------|----------|
| No additive              | Matte | 2094     |
|                          | Slag  | 518      |
| CaO                      | Matte | 1910     |
|                          | Slag  | 641      |
| $\text{Na}_2\text{CO}_3$ | Matte | 2001     |
|                          | Slag  | 550      |
| $\text{Na}_2\text{SO}_4$ | Matte | 1743     |
|                          | Slag  | 795      |
| MgO                      | Matte | 1830     |
|                          | Slag  | 710      |

### 3.2. Converter-furnace

#### 3.2.1. In the matte blowing stage (slag blowing)

Table 11 presents the Pb content detected in products from experiments designed to evaluate the effect of slag-forming agent addition to converter matte. The Just Heat test results indicate that approximately 53% of the Pb is removed from the melt. Notably, Figure 1 shows that the incorporation of slag-forming agents enhances Pb removal from the melt, achieving approximately 77% and 75% Pb removal with the slag-forming agents  $\text{Na}_2\text{SO}_4$  and  $\text{MgO}$ , respectively.

The results of the ANOVA analysis to investigate the effect of slag-forming agents on Pb reduction in the molten matte are presented in Table 12. Figure 2 illustrates the influence of the presence of different slag-forming agents on Pb removal from the molten matte (as derived from the ANOVA results). The statistical analysis indicates that the simultaneous presence of two slag-forming agents,  $\text{Na}_2\text{SO}_4$  and  $\text{SiO}_2$ , has the greatest effect on Pb content in the melt. However, as shown in Figure 3, this combined

effect on the response is positive, and among the slag-forming agents tested,  $\text{SiO}_2$  and  $\text{MgO}$  have the largest individual influence on lead presence in the melt. As illustrated in Figs. 2 and 3,  $\text{MgO}$  emerges as the slag-forming agent that significantly reduces lead content in the melt when considered alone.

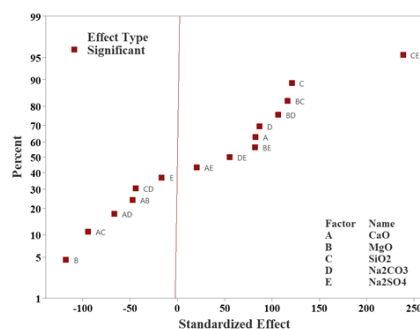

**Table 11. Amount of lead identified in samples from tests designed to remove lead in the matte blowing stage in the converter, achieved through reheating and the addition of various slag-forming agents to the slag**

| Run Order | Experiment set  | Pb   |      |
|-----------|---|------|------|
| 0         | Base matte  | 8370 |      |

**Fig. 2.** Standardized effects illustrating how the presence of different slag-forming agents in the slag from the matte blowing stage of the converter influences the removal of Pb.**Fig. 3.** The type of positive/negative effects of experimental-Design parameters on Pb removal.

In the experiments, the combined use of slag-forming agents SiO<sub>2</sub> and Na<sub>2</sub>SO<sub>4</sub> in the converter furnace is observed to reduce Pb content in the molten matte through chemical reactions that form stable slag compounds. The proposed mechanisms are outlined below.

(i) Na<sub>2</sub>SO<sub>4</sub> reacts with PbO to form stable lead sulfate-containing species:

Lead sulfates are thermodynamically stable at converter temperatures and preferentially partition into the slag.

(ii) Thermal decomposition of Na<sub>2</sub>SO<sub>4</sub> at high temperatures followed by reaction with PbO:

- Partial decomposition of Na<sub>2</sub>SO<sub>4</sub> at elevated temperatures:

- Subsequent reaction of Na<sub>2</sub>O with PbO to form lead-containing slag phases:

Na<sub>2</sub>O acts as a basic slag former and promotes incorporation of Pb into slag phases.

(iii) SiO<sub>2</sub>-PbO-Na<sub>2</sub>O interactions forming lead- and sodium-containing silicates:

- Acidic slag-forming SiO<sub>2</sub> reacts with PbO in the presence of Na<sub>2</sub>O to form silicate compounds:

Silicate phases are thermodynamically stable with high melting points and readily partition into the slag.

### 3.2.2. In the copper (white metal) blowing stage

Table 13 presents results from tests investigating the effect of adding different slag-forming agents on the removal of Pb from molten white metal. As seen, the heating process alone removes only about 11% of the Pb in the melt, which is lower than the removal observed in tests conducted with slag-forming agents. On the other hand, among the slag-forming agents tested, Na<sub>2</sub>CO<sub>3</sub>, MgO, and SiO<sub>2</sub> rank first to third, respectively, in their effectiveness at removing Pb from the melt. In contrast, CaO shows the Pb ability to remove lead. Figure 4 provides a visual comparison of lead removal from molten white metal in the presence of the different slag-forming compounds.

**Table 13. Amount of lead identified in samples from tests designed to remove lead in the copper (white metal) blowing stage in the converter through reheating and adding various slag-forming agents to the slag**

| Run Order | Experiment set  | Pb   |      |
|-----------|---|------|------|
| 0         | White Metal   | 3950 |      |

**Fig. 4. Percent of lead removed from white metal melt in the presence of various slag-forming agents in copper slag-making (WM) in a converter furnace.**

Table 14 presents the ANOVA results for the data in Table 13. Based on the p-values reported in this table, all factors and interactions considered in this analysis are statistically significant. Also, Figure 5 shows the effect of the presence of the various factors on Pb removal from the white metal, as derived from the ANOVA results. Figure 6 illustrates the standardized effects of the slag-forming factors on Pb removal, enabling direct comparison of their respective influences. As seen, the two factors Na<sub>2</sub>CO<sub>3</sub> and MgO exert the strongest opposing influences on Pb removal: Na<sub>2</sub>CO<sub>3</sub> has a positive effect (increasing lead removal), while MgO has a

negative effect (reducing lead removal) on the average residual lead in the melt. Other potential binary interactions that may significantly affect the residual lead include MgO–CaO and Na<sub>2</sub>CO<sub>3</sub>–Na<sub>2</sub>SO<sub>4</sub>. The interpretation suggested by the analysis is:

MgO–CaO: predicted to decrease the residual lead content.

Na<sub>2</sub>CO<sub>3</sub>–Na<sub>2</sub>SO<sub>4</sub>: predicted to increase the residual lead content.

### 3.3. Anodic-Furnace

Table 15 presents the Pb content measured after slagging tests on anodic copper. In the test designed to assess the effect of reheating the melt, approximately 12.5% of the Pb is reduced during this process. Consistent with prior results on Pb removal, the addition of slagging agents significantly decreases the Pb content in the melt. The percentage reduction of Pb from the anodic copper melt across different tests is shown in Figure 7. Notably, among the main slagging agents, SiO<sub>2</sub> exhibits the greatest effect, reducing Pb content by more than 66%. Furthermore, in tests employing multiple slag-forming agents simultaneously, the results indicate very favorable Pb-reduction performance (greater than 79%) in the presence of CaO–MgO–Na<sub>2</sub>CO<sub>3</sub> and MgO–Na<sub>2</sub>SO<sub>4</sub>–SiO<sub>2</sub> systems.

The ANOVA results, aimed at evaluating the interactive effects of slag-forming agents on Pb reduction, are reported in Table 16. The main effects are depicted in Figure 8, while their effect on the average antimony content in the melt is shown in Figure 9. The presented data indicate that the binary combination CaO+Na<sub>2</sub>SO<sub>4</sub> has the largest influence on changing Pb content in anodic copper, although this effect does not translate into a reduction in the average Pb content. Additionally, Na<sub>2</sub>CO<sub>3</sub> emerges as the most effective slag-forming agent among those tested for reducing Pb present in the melt.

Table 15. The amount of Pb detected in samples from tests designed to remove Pb in the anode furnace slag stage through reheating and adding various slag-forming agents to the slag.

| Run Order | Experiment set  | Pb  |     |

Fig. 8. Standardized effect of the presence of different forms of slag-forming agents in anode furnace slag on the removal of harmful element Pb.

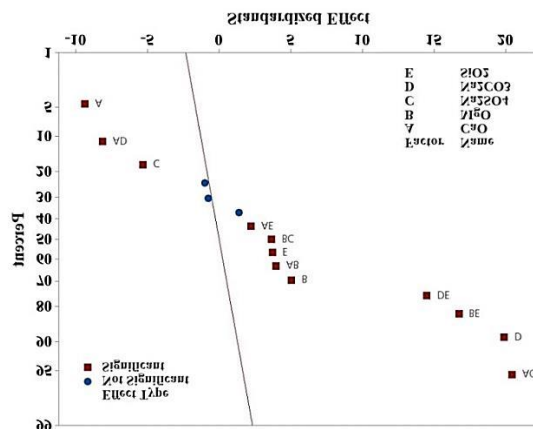

Fig. 9. The type of positive/negative effect of the parameters investigated in the experimental design on the removal of the harmful element Pb from the anodic copper melt.

The slag-forming agent Na<sub>2</sub>CO<sub>3</sub> decomposes upon addition and exposure to high temperature, yielding Na<sub>2</sub>O and CO<sub>2</sub>. The formed Na<sub>2</sub>O subsequently reacts with PbO and SiO<sub>2</sub> to produce stable sodium Pb silicate compounds, such as Na<sub>2</sub>PbSiO<sub>4</sub>, through the Reaction. (6)

On the other hand, SiO<sub>2</sub>, as an acidic slag former, can react with PbO and Na<sub>2</sub>O to form Pb- and Na-containing silicate phases through Reactions (4) and (5), respectively.

### 3.4. Optimizing Pb Removal Process

Since the removal of the Pb impurity in the anode furnace resulted in a reduction of this element to very low levels, the optimal stage for lead removal was also identified as the anodic copper production stage. Considering the high removal percentage observed in the initial experiments and the prediction made by the ANOVA statistical analysis, the slag-forming combination of CaO and Na<sub>2</sub>CO<sub>3</sub> was studied.

Table 17 shows the residual Pb content in the different slag melts in the slag optimization experiments. The lowest lead content (below 100 ppm) in these experiments was related to the samples in which both slag-forming agents were at their highest levels.

Table 17. Residual Pb content in anodic copper melt in slag-forming composition optimization experiments

| RunOrder | CaO | Na <sub>2</sub> CO <sub>3</sub> | Pb  |
|----------|-----|---------------------------------|-----|
| 1        | 1   | 1                               | 168 |

| 20       | 2   | 2                               | 148 |
| 21       | 2   | 3                               | 125 |
| 22       | 2   | 1                               | 138 |
| 23       | 1   | 2                               | 154 |
| 24       | 2   | 3                               | 139 |
| 25       | 1   | 1                               | 155 |
| 26       | 1   | 3                               | 132 |
| 27       | 2   | 3                               | 119 |

The results of the ANOVA analysis of the data from this part of the study are presented in Table 18. The results of this analysis showed that both

slag-forming agents and their dual interaction had a significant effect on the change in the amount of molten lead, and among these factors (as shown in Figs. 10 and 11), CaO had the greatest effect on the removal of molten lead. Figure 11 shows that increasing the amount of both slag-forming agents is accompanied by a decrease in the average amount of Pb in the melt, while high levels of slag-forming agents (20% more than the stoichiometric amount) showed the lowest average amount of lead.

#### 4. CONCLUSIONS

In this study, the removal of the harmful element Pb in the copper smelting and production process was optimized. For this purpose, the influence of various slag-forming agents, including CaO, MgO, SiO<sub>2</sub>, Na<sub>2</sub>CO<sub>3</sub>, and Na<sub>2</sub>SO<sub>4</sub>, was explored across different stages of the production process, including flash, converter, and anode furnaces. A factorial experimental design was employed to investigate the factors and treatment methods. Among the results, the following can be highlighted:

- The results of reheating tests at different stages of the process showed that, although increasing the temperature can be effective in some cases, it cannot reduce the amounts of Pb to the required level. Therefore, the use of slag-forming agents was prioritized at all stages for removing Pb.
- Sodium sulfate (Na<sub>2</sub>SO<sub>4</sub>) exhibited the strongest effect, followed by magnesium oxide (MgO) to decrease in Pb content from matte in the flash furnace. Specifically, Na<sub>2</sub>SO<sub>4</sub> reduced the Pb content in matte exiting the flash furnace from 2094 ppm to a substantially lower value, with MgO also producing a notable reduction to 1830 ppm. Other added agents contributed to lowering the Pb concentration to a lesser extent.
- In experiments conducted to remove Pb during the matte blowing stage in the converter, the combination of slag-forming agents SiO<sub>2</sub> and Na<sub>2</sub>SO<sub>4</sub> in the converter furnace was observed to promote Pb removal through favorable chemical reactions and the formation of stable slag compounds. Silicate species, owing to their thermodynamic stability and high melting points, readily enter the slag and are ultimately separated from the metal phase. Consequently, using SiO<sub>2</sub> in combination with Na<sub>2</sub>SO<sub>4</sub> is considered an effective strategy for separating and removing Pb from molten copper, facilitated by the possible formation of stable compounds in the slag, such as sodium Pb silicate.
- Among the slag agents used to remove Pb in the copper blowing stage, Na<sub>2</sub>CO<sub>3</sub>, MgO, and SiO<sub>2</sub> ranked first to third in terms of success in removing this troublesome element from the melt, respectively. On the other hand, CaO showed the least ability to remove this harmful element.
- In the anode furnace stage, among the main slag formers, SiO<sub>2</sub> had the greatest effect (more than 66%) in reducing the lead

content of molten copper anode. On the other hand, in tests in which several slag formers were used simultaneously, the results presented showed that in the presence of slag formers CaO-MgO-Na<sub>2</sub>CO<sub>3</sub> and MgO-Na<sub>2</sub>SO<sub>4</sub>-SiO<sub>2</sub>, very good results in terms of lead reduction (more than 79%) could be seen.

- The results of the optimization test for the Pb removal process also showed that increasing the amount of both slag-forming agents CaO and Na<sub>2</sub>CO<sub>3</sub> is associated with a decrease in the average lead content in the melt, and among them, high levels of slag-forming agents (20% more than the stoichiometric value) showed the lowest average lead content.
